Abstract. Submersible Centrifugal Pumps are quite common in oil industry. Due to oil production nature, two-phase oil and gas mixture flow throughout SCP. Two-phase flow inside pump diffuser and impeller decreases its lift and efficiency. Literature presents a widely variety of studies regarding the influence of operational parameters, such as void fraction, rotor speed and inlet pressure, into SCP global efficiency. Nevertheless, this influence is strictly related to two-phase flow pattern. The present study evaluates two-phase flow inside pump diffuser and impeller by means of a single bubble flowing through the liquid bulk. An experimental apparatus was designed and built at NUEN facilities. Original pump housing and impeller were replaced by transparent pieces in order to visualize bubbles flowing inside the pump. Bubbles path were followed both to define preference paths as to calculate bubbles velocities. Additional CFD analysis yielded liquid velocities and static pressure through pump impeller.

Keywords: ESP, two-phase flow, drag coefficient, drag force.

1. INTRODUCTION

Petroleum reservoirs are commonly established in offshore fields under high-pressure levels. First years of well production are characterized by pressure levels higher enough so that the oil is able to flow naturally upwards to the production facilities. After years of continuous operation, the pressure level decreases and artificial lift methods become necessary to keep extraction economically viable. Among different techniques employed in this sense, one of the most used worldwide is the electrical submersible pump (ESP).

ESPs are multistage pumps arranged in series. They can be installed inside the actual well or in a deviated well, and sometimes gas is produced together with the oil. It is recognized that the presence of dispersed gas inside the liquid bulk can cause significant performance degradation of centrifugal pumps (Gülich, 2010) leading to an intervention to adjust or change an ESP system. This is a big concern for petroleum companies since it is still unknown how a given ESP handles gas without a huge performance degradation or a complete pump shutdown (Estevam, 2002).

Lea and Bearden (1982) conducted one of the first works to study the performance degradation of ESPs operating with oil and gas. They investigated experimentally an oil well using a reduced number of pump stages, three types of ESPS and water-air and diesel-carbonic gas as fluid models. Among other things, they analyzed the degradation of performance with respect to the liquid flow rate, the gas void fraction and the pump speed. The authors also inspected the occurrence of surging, a phenomenon characterized by a large accumulation of gas inside the pump impeller channels that leads to a remarkable drop in the pump efficiency.

Following the work of Lea and Bearden (1982), some investigators (Estevam, 2002; Sachdeva; 1988; Cirilo, 1998; Barrios, 2007; Gamboa, 2008) analyzed the performance of ESPs under gas-liquid admitting conditions. Particularly, Estevam (2002), Barrios (2007) and Gamboa (2008) used flow visualization technics in order to associate the trends of performance to the behavior of the gas inside the pump, including the situations under a surging condition.

Even though few works are able to provide a deep analysis of the movement of individual bubbles inside the liquid in an impeller channel (Murakami and Minemura, 1974a; Murakami and Minemura, 1974b; Minemura and Murakami, 1980), analysis of the available literature reveals that this problem is affected by a number of variables and, so, much information is still needed to bring further comprehension of the phenomena involved with gas-liquid pumping.

For instance, useful information regarding the proposal of a suitable drag coefficient for bubble flows, in such conditions, is still lacking. The analysis of forces acting on bubbles require the knowledge of factors like the drag force and drag coefficient and, successively, lead to the understanding of gas behavior inside a pump as well as the comprehension about why the presence of gas degrades performance.

In this sense, this work combines numerical and experimental techniques to evaluate evaluated the drag coefficient and the drag force according different experimental conditions.

2. EXPERIMENTAL SETUP

The experimental setup was developed in order to permit the study the dynamics of individual bubbles inside the impeller of a centrifugal pump. A scheme of the loop is presented in Fig. 1.
Figure 1. Experimental loop.

Water is pumped by a booster pump from the liquid reservoir through the circuit, the flow rate of which being measured by a Coriolis flowmeter. Adapted to the pump suction flange, a Plexiglas pipe with a 70mm inner diameter and a length of approximately 20 diameters is used to deliver a developed flow of liquid to the pump. Gas is inserted by means of an air compressor through a porous ceramic piece at the entrance section of the development pipe as indicated, and the length of 20 diameters proved to be sufficient for the bubbles to disperse and rearrange themselves inside the pipe up to the pump suction.

When needed, the air flow rate is measured using an orifice plate in the air admitting tube prior to the bubbles insertion, while the volumetric flow rate can be corrected at the test pump suction flange by measuring the entrance pressure, \( P_e \). Two additional pressure transducers are used to collect the pressure differences across the whole pump, \( P_{\text{diff}} \), and through the rotor alone, \( P_{\text{diff}} \). Downstream of the test pump, a globe valve is used to help regulating the liquid flow rate. Just after it, another pipe drives the gas-liquid mixture back to the reservoir, where phases separate naturally by gravity.

The test pump uses two radial impellers, a diffuser connecting both impellers and a discharge volute. The original pump casing and the first impeller were replaced with transparent materials to permit visualization of the flow of bubbles inside the first stage of the pump. This was accomplished by using a high speed camera focused orthogonally to the pump casing and the pump impeller, with aid of a front illumination provided by a LED spot. An actual photograph of the system is shown in Fig. 2. Signals from all sensors and the booster pump frequency inverter, as well as the images from the high speed camera are controlled, processed and recorded using a dedicated data acquisition system as previously indicated in Fig. 1.

Images were acquired at 1000 fps. Due to intake pipe positioning, the visualization field were limited to only one rotor channel section, ranging 35mm far from pump axis to the end of the rotor. Bubble velocities, at x and y directions, were obtained by images data evaluation.

Figure 2. Photograph of the test pump with transparent casing, the high speed camera and the LED spot.
3. NUMERICAL PROCEDURE

As will be shown later, the drag coefficient will be evaluated by tracking the path of the bubbles inside the impeller channel and comparing the drag force exerted by the liquid over the bubble with the opposite pressure gradient created by the impeller. Numerical simulations of the single-phase flow of water inside the first stage of the test pump were performed in order to accomplish this task. It was assumed that the individual flow of few and small bubbles do not affect appreciably the flow field of water.

Numerical simulations were performed over the commercial package ANSYS® CFX® Release 14.5 (ANSYS, 2012). This computational fluid dynamics (CFD) software uses a finite volume method to solve the mass and momentum equations that govern the problem in question. Flow turbulence is modelled through Reynolds averaging and the standard k-ε model (Launder and Spalding, 1974).

For turbomachinery problems, the referred CFD software employs a multi-block technique in which each part of the pump, static or rotating, comprises a separate domain. Then, information through domains is transferred by means of interface models. This concept is illustrated for the present problem in Fig. 3, where the pump parts considered for this analysis are an inlet pipe (static), the impeller (rotating), a vaned diffuser and an extension of the diffuser channel (both static).

The numerical procedure used to model the rotation of the impeller with respect to the static parts can be accomplished in general by two ways. The first is to actually displace the rotor in small time steps, which is a more conservative and realistic approach and, in turn, very time consuming. An alternative is to keep a fixed reference position between the impeller and the static parts and account for its rotation by using source terms in the governing equations and proper interface models. This last approach results in much less time consuming simulations and was the method assumed in this work. Several details about this procedure can be found in ANSYS (2012) and Stel et al. (2015).

The numerical grid used in the numerical simulations is constructed with hexahedral, body-fitted elements as shown in Fig. 4. Even though the whole 360° domain is shown, the blade number ratio between impeller (8 blades) and diffuser (12 vanes) was taken into account to simulate only 90° of each part with the help of periodicity conditions. More details on this procedure can also be found in ANSYS (2012) and Stel et al. (2015). After running mesh sensitivity tests, it was concluded that a total number of around 718,000 grid nodes is sufficient to give mesh independent results in the scope of the present study, where the impeller alone accounts for 620,000 nodes.

Figure 3. Schematic representation of the multi-block technique assumed for the present problem.

Figure 4. Numerical grid assumed for the present problem. The grid distribution near to the blade is show in detail.
One can notice from Figs. 3 and 4 that only the first stage of the pump is simulated, since it is the only stage for which experimental visualization is possible. An intake pipe is assumed to make the inlet boundary condition far from the impeller eye. The inlet boundary condition was assumed as a 0 [Pa] total pressure (with respect to an ambient pressure of 1 [atm]), while flow rate is imposed at the outlet sections of the diffuser extension. This last piece, in turn, was used to keep the outlet condition far from the diffuser exit, as a way to avoid backward influence on the flow inside the impeller due to the fact that the second stage is disregarded. Walls are considered no-slip but smooth, that is, the effect of the wall roughness being neglected.

4. RESULTS AND DISCUSSION

Results for the bubble motion inside the pump impeller are presented in this section. The drag force resulted from a force balance on the bubble along its trajectory is also of particular interest. Results using the visualization technique are obtained for rotation speeds from 100 to 220 rpm. Table 1 shows the operating conditions assumed for that purpose.

4.1 Pump Performance.

Figure 5 shows the head curve versus flow rate obtained experimentally with the present experimental loop with the pump commercial catalog curve and experimental data from Amaral (2007) for the same pump. All data is evaluated for a rotating speed of 612 rpm.

Figure 5 shows that results agree well within the range analyzed. Specifically for the first stage of the pump, the pressure rise obtained experimentally was compared with the numerical model described in section 3, for which a good agreement was also observed.

4.2 Bubble Trajectory.

Figure 6 shows trajectories of several bubbles obtained using the methodology described in section 2, for different rotating speeds. All data were acquired for liquid flow rates reduced to each rotating speed from the best efficiency point (BEP) flow rate at 1150 rpm assuming regular affinity laws. Bubble trajectory through the impeller channel is evaluated considering a non-inertial frame of reference that rotates with the impeller.

For 100 rpm, bubbles preferentially flow close to the blade suction side as shown in Fig. 6. However, this preferential path is no longer kept if the rotating speed is increased. As one can observe for 170 and 220 rpm, the
bubbles tend to be displaced farther from the suction side in a slightly different behavior in comparison with the 100 rpm case.

Figure 6. Bubbles trajectories inside the impeller channel obtained using the high speed camera for different rotating speeds.

Figure 7. Illustration of the three basic trajectories of individual bubbles inside the impeller channel.

Careful inspection of the images obtained allowed identification of a general set of behavior for the bubbles motions. They generally consist of three basic types of trajectories, which are illustrated in Fig. 7. When a given bubble enters the impeller close to the suction side, it preferentially follows the blade curvature without sensible deviations downstream to the exit. The red line denotes this path. If the bubble starts its motion inside the impeller farther from the suction side than the previous case, say, in the position denoted by the blue line, its trajectory tends to gradually deviate from the blade curvature. Close to the channel outlet, it can be suddenly pushed to the pressure side before exiting the impeller. In turn, if the bubble enters the impeller even farther from the suction side (green line), it tends to be severely
decelerated yet at the channel entrance. A displacement follows to the channel pressure side, and the bubble can be pushed back upstream to the impeller eye.

4.3 Drag Coefficient Estimation.

The methodology of Murakami and Minemura (1974a) was adopted in this paper in order to estimate the drag coefficient consistent with the bubble motion inside the impeller. It is based on a force balance on a bubble flowing alone through an impeller channel with constant relative velocity with respect to the liquid. The authors assumed an equilibrium between the drag force and the pressure gradient force acting in opposite directions on the bubble all along its path, while other interfacial forces are disregarded.

A more comprehensive balance force on a given bubble in a rotating frame of reference is given by Minemura and Murakami (1980) and can be expressed as:

\[
\sum F = f_d + f_p + f_m + f_B + f_g,
\]

where \( f_d \), \( f_p \), \( f_m \), \( f_B \) and \( f_g \) represent the drag force, the pressure gradient force, the virtual mass force, the gravity force and the Basset force. Expressions for these forces and information on how they influence on the problem in question can be found in Minemura and Murakami (1980).

As discussed by Minemura and Murakami (1980), the two major forces acting on the bubble are indeed \( f_d \) and \( f_p \), and this is assumed in the present work. A scheme of the resulting balance is shown in Fig. 8, where an impeller channel is illustrated together with a non-inertial frame of reference and an arbitrary bubble path.

![Figure 8. Force balance over an arbitrary air bubble.](image)

The pressure gradient force, \( f_p \), acts opposite to the bubble motion and arises from the pressure increase in the liquid provided by the impeller. It is proportional to the bubble volume and, when analyzed over the bubble streamline path, is given by:

\[
f_p = B_p \frac{\partial P}{\partial s}
\]

where \( B_p \) is the bubble volume and \( \partial P / \partial s \) is the pressure gradient over the streamline “s” at a given point.

In turn, the drag force acts in the direction of the bubble movement as a result from a difference between the bubble velocity and the surrounding continuum. The expression for this force is given as follows:

\[
f_d = \frac{1}{2} C_d \rho_l (V_{\beta} - V_{\alpha})^2 \frac{\pi d_b^2}{4}
\]

where \( C_d \) is the drag coefficient, \( \rho_l \) is the liquid density, \( V_{\alpha} \) and \( V_{\beta} \) are the local velocity components of the bubble and the liquid in the direction of the streamline path and \( d_b \) is the bubble diameter.

Assuming that the drag and the pressure gradient force are balanced along its trajectory, it follows that:
\[
C_d = \frac{4}{3} \frac{d_b}{\rho \left( V_{ab} - V_s \right)^2} \frac{\partial P}{\partial s}
\]  

(4)

Values of \( \partial P / \partial s \) and \( V_s \) cannot be evaluated using the present experimental loop, and were obtained from the numerical results. This is done by extracting the exact trajectory from the visualization data in each case and further using it to calculate the values of \( \partial P / \partial s \) and \( V_s \) from the numerical results. The estimated drag coefficient, according to different bubble diameters, flow rates and rotating speeds, were compared to the Schiller and Naumann (1933) model:

\[
C_d = \frac{24}{Re} \left(1 + 0.15Re^{0.687} \right)
\]

(5)

where \( Re \) is the bubble Reynolds number based on its relative velocity.

4.4 Drag Coefficient as a Function of the Bubble Diameter.

Figure 9 shows a comparison of the estimated drag coefficient as a function of the bubble Reynolds number for different bubble diameters and three rotating speeds. It can be observed that \( C_d \) increases as the bubble diameter increases. However, this influence is expected to be negligible for high Reynolds numbers, where the drag coefficient tends to a constant, which seems to be the case here as well. The \( C_d \) curve obtained from Eq. (4) for a rotating speed of 120 rpm and a bubble diameter equal to 0.63 mm proved to be the closest with the one obtained with Schiller and Naumann (1933) model. This seems to be consistent with the fact that smaller bubbles are more likely to keep a spherical shape, for which the Schiller and Naumann (1933) model is appropriate.

![Figure 9. Drag coefficient, \( C_d \), versus the bubble Reynolds number, \( Re \), for different bubble diameters and rotating speeds.](image)

4.5 Drag Coefficient as a Function of the Liquid Flow Rate.

Figure 10 shows the estimated drag coefficient as a function of the bubble Reynolds number for different liquid flow rates and two different rotating speeds. All cases are obtained for the same bubble diameter. As one can observe from Figs. 10 (a) and (b), the liquid flow rate has negligible influence on the \( C_d \) behavior.
4.6 Drag Coefficient as a Function of the Rotating Speed.

Figure 11 compares now the drag coefficient curve obtained for different rotating speeds, all for a flow rate consistent to the best efficiency point, for the same bubble diameter (namely 0.96 mm). It can be noticed that the drag coefficient increases with the impeller speed for a given Reynolds number. It should be noted, however, that the liquid flow rate at the best efficiency point also increases with the rotating speed, according to affinity laws. The actual effect of the rotating speed on the drag coefficient, as well as a deeper exploration of both the experimental results and the numerical model used in this work are subject of further works from the present group of authors.

5. CONCLUSIONS

This work presented an analysis of the dynamics of bubbles moving through a liquid phase inside a centrifugal pump impeller. High-speed visualization (HSV) was used to observe the motion of bubbles inside the pump, while an algorithm was developed to compute the bubble trajectory, velocity and diameter for several operating conditions. A numerical model was also used to calculate the pressure and velocity flow fields inside the pump for liquid single-phase flows, which proved to be a useful tool to help obtaining estimations for the drag coefficients of the bubbles inside the impeller channels.

Distinct behaviors were identified for the bubbles motions inside the impeller, which are very sensitive to the position where the bubbles enter the impeller. In general, bubbles that flows close to the impeller suction side tend to follow the blade curvature, while the ones that enter the impeller at middle positions between blades may be severely deflected inside the hydraulic channel. Experimental results showed that the bubble diameter and the impeller rotating
speed have a discernible effect on the drag coefficient, whereas negligible influence is observed with respect to the liquid flow rate. Deeper exploration of these influences and a more general description of the phenomenon are ongoing subjects of the present authors.
